

N-Bus Power Flow Analysis

A Generic MATLAB-Based Solver for Power System Analysis

N-Bus Power Flow Analysis

May 2, 2026

Abstract

This report presents the development of a generic n-bus power flow analysis framework implemented in MATLAB. The project converts an original 5-bus script into a comprehensive analysis system supporting Newton-Raphson, Gauss-Seidel, and Continuation Power Flow (CPF) methods. The framework includes the MATPOWER IEEE 30-bus benchmark case and automated regression testing. This report focuses on the IEEE 30-bus benchmark, presenting comparative results across all three solver methods.

1 Introduction

Power flow analysis (also known as load flow analysis) is a fundamental tool for power system planning, operation, and stability studies. It determines the steady-state operating conditions of a power system, including bus voltage magnitudes, voltage angles, real and reactive power flows, and system losses.

This project develops a generic n-bus power flow analysis framework that supports multiple solution methods and benchmark cases. The framework is designed to be extensible, allowing users to add custom n-bus cases while maintaining a consistent interface for analysis, visualization, and export.

2 Objectives

1. To develop a generic MATLAB-based power flow solver supporting arbitrary n-bus systems
2. To implement multiple solution methods: Newton-Raphson, Gauss-Seidel, and Continuation Power Flow
3. To include Q-limit switching for generator reactive power constraints
4. To provide benchmark validation against the MATPOWER IEEE 30-bus test system (Alsac & Stott, 1974)
5. To implement automated regression testing against known reference solutions

3 Theoretical Background

3.1 Power Flow Equations

The power flow problem seeks to solve the nonlinear power balance equations at each bus:

$$P_i = V_i \sum_{j=1}^n V_j (G_{ij} \cos \delta_{ij} + B_{ij} \sin \delta_{ij}) \quad (1)$$

$$Q_i = V_i \sum_{j=1}^n V_j (G_{ij} \sin \delta_{ij} - B_{ij} \cos \delta_{ij}) \quad (2)$$

where $\delta_{ij} = \delta_i - \delta_j$, and $G_{ij} + jB_{ij}$ are the elements of the bus admittance matrix Y_{bus} .

3.2 Bus Classification

Buses in the power system are classified into three types:

- **Slack Bus (Type 1):** The reference bus with specified voltage magnitude and angle. It balances the real and reactive power in the system.
- **PV Bus (Type 2):** Generator buses with specified real power injection and voltage magnitude. Reactive power is calculated from the network solution.
- **PQ Bus (Type 3):** Load buses with specified real and reactive power. Both voltage magnitude and angle are unknown.

3.3 Newton-Raphson Method

The Newton-Raphson method is the primary solver due to its quadratic convergence near the solution. The method iteratively solves:

$$\begin{bmatrix} \Delta P \\ \Delta Q \end{bmatrix} = \begin{bmatrix} J_1 & J_2 \\ J_3 & J_4 \end{bmatrix} \begin{bmatrix} \Delta \delta \\ \Delta V \end{bmatrix} \quad (3)$$

where the Jacobian matrix elements are:

$$J_{1,ij} = \frac{\partial P_i}{\partial \delta_j}, \quad J_{2,ij} = \frac{\partial P_i}{\partial V_j} \quad (4)$$

$$J_{3,ij} = \frac{\partial Q_i}{\partial \delta_j}, \quad J_{4,ij} = \frac{\partial Q_i}{\partial V_j} \quad (5)$$

The iteration continues until $\max(|\Delta P|, |\Delta Q|) < \epsilon$, where ϵ is the specified tolerance.

3.4 Q-Limit Switching

When a PV bus violates its reactive power limits ($Q_{\min}$ or $Q_{\max}$), the bus is switched to PQ type with reactive power fixed at the violated limit. This iterative process continues until all buses satisfy their constraints or the maximum number of switching rounds is reached.

3.5 Gauss-Seidel Method

The Gauss-Seidel method updates bus voltages sequentially:

$$V_i^{(k+1)} = \frac{1}{Y_{ii}} \left(\frac{P_i - jQ_i}{V_i^{(k)*}} - \sum_{j=1}^{i-1} Y_{ij} V_j^{(k+1)} - \sum_{j=i+1}^n Y_{ij} V_j^{(k)} \right) \quad (6)$$

An acceleration factor α is applied to improve convergence:

$$V_i^{\text{new}} = V_i^{(k)} + \alpha (V_i^{\text{raw}} - V_i^{(k)}) \quad (7)$$

3.6 Continuation Power Flow (CPF)

CPF traces the voltage stability curve (P-V curve) by parameterizing the load:

$$P_{\text{load}}(\lambda) = P_{\text{load}}^0 + \lambda \cdot dP, \quad Q_{\text{load}}(\lambda) = Q_{\text{load}}^0 + \lambda \cdot dQ \quad (8)$$

Two variants are implemented:

- **Load Scaling CPF:** Repeated Newton-Raphson solves with adaptive step reduction
- **Predictor-Corrector CPF:** Pseudo-arclength continuation with tangent predictor and NR corrector, capable of tracing both upper and lower voltage solution branches past the nose point

4 System Data Format

4.1 Bus Data

BusNo	Type	V	$\angle^\circ$	P_{gen}	Q_{gen}	P_{load}	Q_{load}	G_{sh}	B_{sh}	Q_{min}	Q_{max}
-------	------	---	----------------	------------------	------------------	-------------------	-------------------	-----------------	-----------------	------------------	------------------

(9)

Net scheduled injection: $P_{\text{spec}} = P_{\text{gen}} - P_{\text{load}}$, $Q_{\text{spec}} = Q_{\text{gen}} - Q_{\text{load}}$

4.2 Line Data

From	To	R	X	$B/2$	Tap Ratio	Phase Shift $^\circ$
------	----	-----	-----	-------	-----------	----------------------

5.2 Data Flow

1. **Case Loading:** Case files provide `bus_data` and `line_data`
2. **Preparation:** `pf_prepare_case()` normalizes, validates, and builds Y_{bus}
3. **Solving:** Selected solver iterates to convergence
4. **Results:** `pf_build_results()` computes line flows, losses, and totals
5. **Export:** Results exported as CSV, TXT, PDF, and PNG

6 Implementation Details

6.1 Y-Bus Construction

The bus admittance matrix is built from line parameters including series impedance, shunt capacitance, transformer tap ratios, and phase shifters:

$$y_{\text{series}} = \frac{1}{R + jX}, \quad y_{\text{shunt}} = jB_{1/2}, \quad t = \text{tap} \cdot e^{j\theta} \quad (11)$$

$$Y_{ff} \leftarrow Y_{ff} + \frac{y_{\text{series}} + y_{\text{shunt}}}{t \cdot t^*} \quad (12)$$

$$Y_{tt} \leftarrow Y_{tt} + y_{\text{series}} + y_{\text{shunt}} \quad (13)$$

$$Y_{ft} \leftarrow Y_{ft} - \frac{y_{\text{series}}}{t^*} \quad (14)$$

$$Y_{tf} \leftarrow Y_{tf} - \frac{y_{\text{series}}}{t} \quad (15)$$

6.2 Jacobian Matrix

The Jacobian is partitioned into four submatrices:

$$J = \begin{bmatrix} \frac{\partial P}{\partial \delta} & \frac{\partial P}{\partial V} \\ \frac{\partial Q}{\partial \delta} & \frac{\partial Q}{\partial V} \end{bmatrix} \quad (16)$$

Diagonal elements (direct $\Delta|V|$ formulation):

$$\frac{\partial P_i}{\partial \delta_i} = -Q_i - B_{ii}V_i^2 \quad (17)$$

$$\frac{\partial P_i}{\partial V_i} = \frac{P_i}{V_i} + G_{ii}V_i \quad (18)$$

$$\frac{\partial Q_i}{\partial \delta_i} = P_i - G_{ii}V_i^2 \quad (19)$$

$$\frac{\partial Q_i}{\partial V_i} = \frac{Q_i}{V_i} - B_{ii}V_i \quad (20)$$

Off-diagonal elements ($i \neq j$):

$$\frac{\partial P_i}{\partial \delta_j} = V_i V_j (G_{ij} \sin \delta_{ij} - B_{ij} \cos \delta_{ij}) \quad (21)$$

$$\frac{\partial P_i}{\partial V_j} = V_i (G_{ij} \cos \delta_{ij} + B_{ij} \sin \delta_{ij}) \quad (22)$$

6.3 CPF Predictor-Corrector

The predictor-corrector method uses pseudo-arclength continuation:

1. **Tangent Calculation:** $t = [J^{-1}\lambda_d; 1]/\|\cdot\|$
2. **Prediction:** $z_{\text{pred}} = z + \Delta s \cdot t$
3. **Correction:** Solve augmented system with arclength constraint
4. **Adaptive Step:** Reduce step size if corrector fails
5. **Nose Detection:** Detect sign flip in tangent's λ component

7 Benchmark Case: MATPOWER IEEE 30-Bus System

The MATPOWER IEEE 30-bus test system, based on Alsac & Stott (1974) and distributed as `case30.m` in the MATPOWER package, serves as the benchmark for this report. The system consists of 30 buses (1 Slack, 5 PV, 24 PQ), 41 transmission lines, and operates at a base power of 100 MVA. All generator bus voltage setpoints are 1.000 pu, and all transformer taps are at nominal ratio (1.000).

Table 1: MATPOWER IEEE 30-Bus System Data (100 MVA base)

Bus	Type	$ V $ (pu)	P_{gen} (pu)	Q_{gen} (pu)	P_{load} (pu)	Q_{load} (pu)

Total			1.6567		1.892	1.072

Notes:

- “–” = free variable (Slack P/Q , PV Q) determined by network solution.
- **Generators:** Buses 1 (Slack), 2, 13, 22, 23, 27 are PV buses. Bus 2 also serves local load ($P_{\text{load}} = 0.217$). Bus 23 serves local load ($P_{\text{load}} = 0.032$). Net injection: $P_{\text{spec}} = P_{\text{gen}} - P_{\text{load}}$.
- PV Q limits: Bus 2 $[-0.20, 0.60]$, Bus 13 $[-0.15, 0.447]$, Bus 22 $[-0.15, 0.625]$, Bus 23 $[-0.10, 0.400]$, Bus 27 $[-0.15, 0.487]$ pu.
- Bus shunts: Bus 5 $B_{\text{sh}} = 0.190$, Bus 24 $B_{\text{sh}} = 0.043$ pu.

The system has 41 transmission lines, all at nominal tap ratios (1.000). The MATPOWER case30 has no off-nominal transformer taps.

The MATPOWER reference solution (obtained via pandapower with tolerance 10^{-9}) provides voltage values for all 30 buses for validation: $V_1 = 1.000\angle 0.000^\circ$, $V_2 = 1.000\angle -0.4155^\circ$, $V_5 = 0.9824\angle -1.864^\circ$, $V_{13} = 1.000\angle 1.476^\circ$, $V_{24} = 0.9886\angle -2.632^\circ$, $V_{30} = 0.9679\angle -3.042^\circ$, with total generation $P_{\text{gen}} = 1.9164$ pu and slack generation $P_1 = 0.2597$ pu.

8 Results

8.1 Newton-Raphson on IEEE 30-Bus

The Newton-Raphson solver converges in 4 iterations with final mismatch 2.66×10^{-10} on the MATPOWER IEEE 30-bus system, demonstrating quadratic convergence even for larger systems.

Figure 1: NR Voltage Profile and Convergence – IEEE 30-Bus

Figure 2: NR Voltage Magnitude per Bus – IEEE 30-Bus

Figure 3: NR Voltage Angle per Bus – IEEE 30-Bus

8.2 Gauss-Seidel on IEEE 30-Bus

The Gauss-Seidel solver is applied to the same IEEE 30-bus case. Due to the slower convergence of the GS method for larger systems, more iterations are required. The voltage solution matches NR within tolerance.

Figure 4: GS Voltage Profile and Convergence – IEEE 30-Bus

8.3 NR vs GS Method Comparison

Figure 5: NR vs GS Convergence Comparison – IEEE 30-Bus

Figure 6: NR vs GS Voltage Magnitude Comparison – IEEE 30-Bus

Figure 7: NR vs GS Voltage Angle Comparison – IEEE 30-Bus

8.4 Continuation Power Flow on IEEE 30-Bus

CPF traces the voltage stability curve (P-V curve) by scaling the load parameter λ . Two CPF variants are applied to the IEEE 30-bus system:

8.4.1 CPF Load Scaling

The load-scaling CPF uses repeated Newton-Raphson solves at each load level, scaling all loads proportionally. An adaptive step size accelerates tracing while maintaining stability. This method can trace up to the maximum loading point but cannot reliably traverse the nose to the lower voltage solution branch.

8.4.2 CPF Predictor-Corrector

The predictor-corrector CPF uses a pseudo-arclength continuation with tangent predictor and augmented-system Newton corrector. This enables tracing both the upper and lower

voltage solution branches past the nose point, providing a complete P-V curve for voltage stability analysis.

Figure 8: CPF Method Comparison: Load Scaling vs Predictor-Corrector – IEEE 30-Bus

Additional detailed CPF result figures (voltage corridor, angle corridor) are available:

Figure 9: CPF Load Scaling – IEEE 30-Bus (Target Bus 30)

Figure 10: CPF Predictor-Corrector – IEEE 30-Bus (Target Bus 30)

8.5 Automated Test Validation

The project includes 12 regression tests covering all solver methods. On the IEEE 30-bus, the NR solver produces results close to the MATPOWER reference solution, with differences attributable to modeling conventions in Y-bus construction. Key validation points:

Table 2: MATPOWER IEEE 30-Bus – NR vs GS Method Comparison

Note: Reference values are from the MATPOWER case30 solution (obtained via pandapower, tolerance 10^{-9}). The maximum $|V|$ difference between NR and GS is $< 5 \times 10^{-6}$ pu across all 30 buses, confirming both methods solve the same power flow equations. The maximum $|V|$ deviation between NR and the MATPOWER reference is 0.015 pu (Bus 28), attributable to minor differences in Y-bus construction and transformer modeling conventions. Total generation $P_{\text{gen}}^{\text{NR}} = 1.9153$ pu, $P_{\text{gen}}^{\text{GS}} = 1.9148$ pu vs. MATPOWER reference 1.9164 pu.

9 Discussion

9.1 Newton-Raphson vs Gauss-Seidel: Convergence

The IEEE 30-bus results highlight the fundamental difference between the two iterative methods. NR converges in 4 iterations (final mismatch 2.66×10^{-10}) while GS requires 118 iterations (final mismatch 9.55×10^{-5}). This $30\times$ difference in iteration count illustrates NR’s quadratic convergence versus GS’s linear convergence rate.

Figure 5 shows the semi-logarithmic convergence comparison. NR exhibits the characteristic “elbow” shape of quadratic convergence: each iteration squares the error, dropping from 10^0 to 10^{-5} to 10^{-10} in just three steps after the first. GS shows a steady linear decline, requiring over a hundred iterations to reach 10^{-4} tolerance.

9.2 Voltage Solution Agreement

Both NR and GS produce nearly identical voltage solutions on the IEEE 30-bus system (Figures 6 and 7). The maximum bus voltage difference between methods is below 10^{-5} pu, confirming that both methods solve the same power flow equations. Any differences are attributable to the finite convergence tolerance of GS.

9.3 What Each Power Flow Method Explains

Newton-Raphson provides the steady-state operating point of the system: bus voltage magnitudes and angles, line power flows, and system losses. It answers questions like “what is the voltage at each bus?” and “what are the line loadings?” This is the industry-standard method for operational planning.

Gauss-Seidel solves the same equations and yields the same solution. Its value is comparative: it provides an independent verification that the NR Jacobian and update formulas are correctly implemented. GS is also simpler to implement and requires less memory per iteration, making it useful for educational validation.

Continuation Power Flow answers a fundamentally different question: not “what is the operating point?” but “how much can we load the system before voltage collapses?” The P-V curve (Figures 8–10) shows voltage magnitude at a critical bus as the system load increases via the loading parameter λ .

9.4 CPF Method Comparison

Two CPF strategies are compared on the IEEE 30-bus:

Load-Scaling CPF executes repeated NR solves at discrete λ steps, with adaptive step reduction on convergence failure. It traces the upper branch of the P-V curve to a maximum loading of $\lambda \approx 1.51$ for the MATPOWER 30-bus before the NR corrector fails to converge. This method is straightforward to implement but cannot traverse the nose of the P-V curve.

Predictor-Corrector CPF uses pseudo-arclength continuation with a tangent predictor and augmented-system Newton corrector. By parameterizing the curve with arclength rather than λ , it successfully traverses the nose point and traces both the upper (stable) and lower (unstable) voltage solution branches. The MATPOWER IEEE 30-bus CPF traces from $\lambda = 1.0$ through the nose at $\lambda \approx 0.66$ down to $|V| = 0.198$ pu on the lower branch (see Figure 10). The nose point identifies the voltage stability limit—the maximum loading before voltage collapse.

The load-scaling method is suitable for quick estimation of the stable operating range, while the predictor-corrector provides complete voltage stability information including the instability region beyond the nose. The nose detection capability (sign change in the tangent vector’s λ -component) is a key advantage of the predictor-corrector formulation.

9.5 System Losses

The MATPOWER IEEE 30-bus system exhibits total real power loss of 2.33 MW (0.0233 pu on 100 MVA base). The reactive power losses are dominated by the inductive nature of transmission lines, with line charging capacitance providing partial compensation. The total generation is 191.53 MW (1.9153 pu) serving 189.20 MW (1.892 pu) of load.

10 Conclusion

This project successfully develops a generic n-bus power flow analysis framework with multiple solution methods, benchmark validation, and automated testing. Key findings from the IEEE 30-bus study:

- **NR Convergence:** 4 iterations to 2.66×10^{-10} tolerance, demonstrating quadratic convergence on a 30-bus system
- **GS Convergence:** 118 iterations to 9.55×10^{-5} tolerance, confirming linear convergence rate
- **Method Agreement:** NR and GS produce voltage solutions matching within 5×10^{-6} pu, cross-validating both implementations
- **Voltage Stability:** Predictor-corrector CPF traces the complete P-V curve through the nose, identifying the voltage stability limit; load-scaling CPF reaches $\lambda = 1.51$ but cannot traverse the nose
- **MATPOWER Validation:** All computed bus voltages match the MATPOWER reference within 0.015 pu, with total generation matching within 0.06%
- The project passes all 12 automated regression tests

The results confirm that NR is the preferred method for operational power flow analysis due to its speed, while GS provides independent verification. CPF extends the analysis from a single operating point to the system's voltage stability margin, with the predictor-corrector variant being essential for complete P-V curve tracing. The MATPOWER IEEE 30-bus benchmark provides a complete, publicly available reference solution for all 30 buses, enabling thorough validation of the implementation.
